Tom Britton Introduction to inference for epidemic outbreaks

## Estimation from one large outbreak

Assume a homogeneously mixing community and no preventive measures

**From before**: in case of a large outbreak and assuming everyone was initially susceptible, the final fraction infected will be close to the positive solution of

$$1-\tau = e^{-R_0\tau}$$

Inference other way around: we observe that a fraction  $\tilde{\tau}$  got infected. What is  $R_0?$ 

Rewrite the equation:  $R_0 = -\ln(1- au)/ au$ 

Our estimate of  $R_0$  is given by the corresponding observed value:

$$\hat{\textit{R}}_0 = -\ln(1- ilde{ au})/ ilde{ au}$$

**Exercise 14**: Estimate  $R_0$  if 20% were infected during an outbreak

#### Estimation from one large outbreak

This estimate assumed everyone was initially susceptible!

If in fact a fraction r was initially immune we know from before that  $\tau$ , the fraction *among the initially susceptible* who got infected approximately equals positive solution of

$$1-\tau = e^{-R_0(1-r)\tau}$$

This leads to the estimate:

$$\hat{R}_0 = -\ln(1- ilde{ au})/(1-r) ilde{ au}$$

**Note:** The over all fraction infected equals  $\tilde{\tau}(1-r)$ 

**Exercise 15**: Suppose as before that 20% were infected during an outbreak, but that only 50% were initially susceptible and the rest were immune. Compute first  $\tilde{\tau}$  and then estimate  $R_0$ 

#### Estimation of $v_c$ from one large outbreak

It was shown earlier that:  $v_c = 1 - 1/R_0$ 

By observing an outbreak we can hence also estimate  $v_c$  (for the same or similar community but not for any community!):

$$\hat{v}_c = 1 - rac{1}{\hat{R}_0} = 1 - rac{ ilde{ au}}{-\ln(1- ilde{ au})}$$

If a fraction r was immune in the observed outbreak and  $\tilde{\tau}$  of the initially susceptibles were infected this changes to

$$\hat{
u}_c = 1 - rac{1}{\hat{R}_0} = 1 - rac{(1-r) ilde{ au}}{-\ln(1- ilde{ au})}$$

#### Estimation of $v_c$ from one large outbreak

If vaccine not perfect but efficacy E known  $v_c$  estimated by

$$\hat{v}_c = \frac{1}{E} \left( 1 - \frac{1}{\hat{R}_0} \right) = \frac{1}{E} \left( 1 - \frac{(1-r)\tilde{\tau}}{-\ln(1-\tilde{\tau})} \right)$$

**Exercise 16**. Suppose as previous exercise that 20% of the community got infected but the initial fraction susceptible was 50% (so 40% of these susceptibles were infected). Estimate the critical vaccination coverage for a vaccine having 90% efficacy.

#### Repetition: Inference from large outbreaks

From before: basic reproduction number  $R_0$  and critical vaccination coverage  $v_c$  were estimated by:

$$egin{aligned} \hat{\mathcal{R}}_0 &= -\ln(1- ilde{ au})/ ilde{ au} \ \hat{\mathcal{v}}_c &= 1-rac{ ilde{ au}}{-\ln(1- ilde{ au})} \end{aligned}$$

if outbreak takes place in a fully susceptible homogeneous community resulting in a fraction  $\tilde{\tau}$  getting infected during the outbreak

How about uncertainty?

#### Uncertainty of previous estimate

Intuition: The larger community (and more getting infected) the less uncertainty

It was mentioned that final number infected  $n\tilde{\tau} = Z$  in case of a major outbreak is normally distributed with mean  $n\tau^*$  and standard deviation  $\sqrt{n\sigma^2}$  where  $\sigma^2$  depends on model parameters and shown two slides ahead

This result can be used to show that  $\hat{R}_0$  and  $\hat{v}_c$  are normally distributed with correct means (i.e.  $R_0$  and  $v_c$  respectively) and standard errors to be derived using  $\delta$ -method

#### The $\delta$ -method

Suppose random variable X has mean  $\mu = E(X)$  and variance V(X). Suppose further that we are mainly interested in the distribution of f(X) for some function  $f(\cdot)$  rather than X itself

Then the  $\delta$ -method gives the following approximation for the mean and variance of f(X), where f(x) is a "nice function":

**Main idea** Taylor expand X around its mean  $\mu$ :  $f(X) \approx f(\mu) + (X - \mu)f'(\mu)$ . This implies:

 $E(f(X)) \approx f(\mu)$   $V(f(X)) \approx (f'(\mu))^2 V(X).$ 

The approximation holds better the smaller variance X has (i.e. smaller V(X)).

We will use it for e.g.  $f(X) = -\ln(1-X)/X$  and with  $X = \tilde{\tau}$  so that  $f(\tilde{\tau}) = \hat{R}_0$ 

## The $\delta$ -method for $V(\hat{R}_0)$

Probabilists have proven that the asymptotic variance of  $\tilde{\tau}$  equals:

$$V( ilde{ au}) pprox rac{1}{n} rac{ au(1- au)}{(1-(1- au)R_0)^2} \left(1+c_
u^2(1- au)R_0^2
ight)$$

where  $\tau$  and  $R_0$  are the true parameter values related by  $R_0 = -\ln(1-\tau)/\tau$ , and  $c_v$  is the coefficient of variation of the infectious period.

We now apply the  $\delta$ -method on  $\hat{R}_0 = -\ln(1-\tilde{\tau})/\tilde{\tau}$ , we hence have the function  $f(x) = -\ln(1-x)/x$ 

After some algebra we get  $V(\hat{R}_0) pprox rac{1}{n au(1- au)} \left(1+c_{
m v}^2(1- au) R_0^2
ight)$ 

For a standard error estimate we take square roots and replace unknown quantities with there estimates/observed values. The result, also for  $\hat{v}_c$ , is given by:

#### Uncertainty of previous estimate

$$s.e.(\hat{R}_{0}) = \sqrt{\frac{1 + c_{v}^{2}(1 - \tilde{\tau})\hat{R}_{0}^{2}}{\tilde{\tau}(1 - \tilde{\tau})}/n}$$
$$s.e.(\hat{v}_{c}) = \sqrt{\frac{1 + c_{v}^{2}(1 - \tilde{\tau})\hat{R}_{0}^{2}}{\hat{R}_{0}^{4}\tilde{\tau}(1 - \tilde{\tau})}/n}$$

 $c_v^2 = V(I)/(E(I))^2$  = squared coefficient of variation of infectious period of individuals (variance divided by the squared mean)

Larger *n* gives smaller standard deviation (as expected)!

#### Uncertainty of previous estimate

 $c_{\nu}^2$  cannot be estimated from final outbreak size – possibly known from before

If not one has to insert a "conservative" bound. E.g.  $c_v^2 = 1$ : very rarely is standard deviation larger than mean

**Exercise 25** Suppose that 239 out of 651 individuals in an isolated village were infected during an outbreak. Estimate  $R_0$  and  $v_c$  and give 95% confidence interval for the estimates. Consider both the case when all individuals have the same length of infectious period (so no variation) and the case where its standard deviation is equal to the mean.

**Exercise 26** Do the same thing assuming 2390 out of 6510 got infected.

#### Estimation in the early phase of an epidemic

**The initial growth**: During the early phase of an epidemic incidence as well as prevalence typcially grows exponentially:

$$I(t) \sim e^{rt}$$

 $\rho$  (or r) called the **Malthusian parameter** 

 $\rho$  depends both on  $R_0$  and the generation time distribution  $g_0(s)$ Branching process theory:  $\rho$  solution to Euler-Lotka equation

$$R_0\int_0^\infty e^{-
ho s}g_0(s)ds=1$$

So if we know the generation time distribution  $g_0(\cdot)$  we can estimate  $R_0$  from observing the exponential growth  $\rho$ !

It is easy to show that if  $g_0(s) \sim \Gamma(\alpha, \beta)$  then Euler-Lotka gives that

$${\cal R}_0=\left(rac{
ho}{eta}+1
ight)^lpha$$
 , where  ${\cal R}_0$  is the set of th

#### Covid-19: $R_0$ estimates, first wave (original strain)

Covid-19: A common estimate is that  $g_0(s) \sim \Gamma$  with mean 6.5 days and s.d. 4 days (see however below!). We assume this to apply to all countries!

We estimate "country" specific  $\rho$  from reported cumulative case fatalities: starting first day with > 50 cumulative case fatalities ( $C_1$ ) and two weeks later  $C_{15}$  case fatalities:  $\hat{\rho} = \ln(C_{15}/C_1))/14$  (Data: Worldometer)

Common dates: first half of March to end of March (before effects of lockdown)

When 50 have died, between 5 000 and 20 000 had been infected so not VERY early in epidemic which is usually atypical and faster (Norway and Denmark: start instead when > 10 have died)

#### Covid-19: R<sub>0</sub> estimates, cont'd

Country	<i>C</i> <sub>1</sub>	<i>C</i> <sub>15</sub>	$\hat{ ho}$	Â <sub>0</sub>	ĥ <sub>C</sub>
" Norway"	12	89	0.14	2.2	54%
" Denmark"	13	161	0.18	2.6	62%
" Sweden"	62	687	0.17	2.5	60%
" Germany"	68	1275	0.21	3.0	67%
" Belgium"	67	1283	0.21	3.0	67%
" UK"	65	2043	0.25	3.5	71%
" Spain"	55	3647	0.30	4.3	77%

 $(h_C = critical vaccination coverage for herd immunity)$ 

 $\implies$  There is not one correct  $R_0$  for covid-19!!

Big differences also within countries! (Sweden starting when > 10 had died gave  $\hat{R}_0 = 3.1$ )

#### Problems with estimating $g_0(s)$ and its consequences

Details: see Britton & Scalia Tomba (2019)

How estimate generation time distribution  $g_0(s)$ ?

Answer: **Contact tracing**: For some identified cases, it is traced by whom and when they were infected

This gives some observed generation times  $g_1, \ldots, g_k$ . This is often only way, but problematic:

- Generation time defined forward in time but contact tracing backward in time. Problematic?
- For some cases a unique infector and infection time is identified, but for some there are several possibilities (and some have none)
- onset of symptoms more common to observe than infection times
- Identified cases are often severe cases. Do mild/asymptomatic cases have same generation times?

#### Toy example

Suppose that  $R_0 = 2$ , and each infected infects one individual after 1 week and one individual after 2 weeks ( $g_0(1) = g_0(2) = 0.5$ )

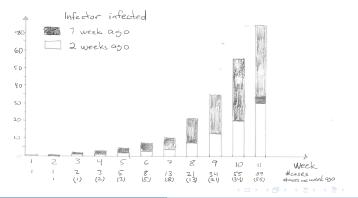

What is E(G)?

#### Toy example

Suppose that  $R_0 = 2$ , and each infected infects one individual after 1 week and one individual after 2 weeks ( $g_0(1) = g_0(2) = 0.5$ )

What is E(G)? 1.5 weeks, and st.d.(G)? 0.5 weeks (below plot of # infections each week)

Tom Britton

Introduction to inference for epidemic outbreaks

#### Looking backwards: contact tracing

Fibonacci numbers and the Golden ratio ...

 $\implies$  The mean generation time when contact tracing will be < 1.5 So if you estimate E(G) (or all of G) from contact tracing you will under-estimate E(G)

#### Generation times vs Serial intervals

#### Serial intervals instead of generation times

(We now forgetproblem of looking backwards)

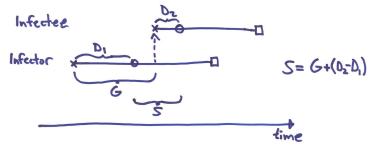

Infection times are hardly ever observed, but onset of symptoms are

- G =time between infection times (unobserved)
- S = time between onset of symptoms (observed)

#### Generation times vs Serial intervals, cont'd

Generaton times vs Serial intervals

#### Generation times vs Serial intervals, cont'd

 $\implies$   $S = G + (D_2 - D_1)$  ( $D_1$  and  $D_2$  = incubation periods of infector and infectee)

So, if incubation times are independent and independent of G, then

E(S) = E(G), and  $V(S) \ge V(G)$ 

(The relation holds true for all (?) epidemic models)

So, if we estimate  $G \sim \{g_0(s)\}$  from observations on Serial intervals we will *over-predict* variance of *G* 

#### Multiple exposures

Another problem when contact tracing is that sometimes there are several potential infectors (see illustration on next slide)

If observations with more than one infected are neglected, remaining intervals are biased from below.

This will also lead to *under-estimation* of E(G)

**Conclusions**: looking backwards and neglecting multiple exposures lead to **under-estimation** of E(G) and observing serial intervals rather than generation intervals lead to **over-estimation** of V(G)

We now see how this can affect estimates of  $R_0$ 

#### Effects of bias in estimates of $g_0(s)$

I(t) = incidence day t = # infected day t (now discrete time)

How many that get infected day t depends on:  $R_0 =$ , basic reproduction number and  $\{g_0(s)\} =$  Generation time

- how many that got infected s days ago? Answer: = I(t - s)

#### Model definition (common model)

$$I(t) \sim \operatorname{Pois}\left(R_0 \sum_{s=1}^{t} g_0(s)I(t-s)\right), t = 1, 2...,$$
 (\*)

"Pois( )" means Poisson distribution, and the mean equals the parameter,  $R_0 \sum_{s=1}^{t} g_0(s) I(t-s)$ 

**Exercise 17.c**: Show that this is more or less identical to the Euler-Lotka equation (Hint: replace the Poisson random variable by its mean)

#### Effects of bias in estimates of $g_0(s)$ (cont'd)

$$I(t) \sim \operatorname{Pois}\left(R_0 \sum_{s=1}^t g_0(s)I(t-s)\right), t = 1, 2...,$$
 (\*)

If  $\{g_0(s)\}$  known (or estimated), Eq. (\*) can be used for:

1: Estimating  $R_0$  (from observed incidence  $I(1), \ldots, I(t)$ ), or 2: Predicting outbreak incidence  $I(1), \ldots, I(t)$  (if  $R_0$  known before-hand)

Both 1 and 2 require knowledge about  $\{g_0(s)\}$ 

**Main question**: How to estimate generation time distribution  $\{g_0(s)\}$  and what happens to estimates of  $R_0$  (or predictions I(1), I(2), ...) if  $\{g_0(s)\}$  is estimated incorrectly?

#### Effects of bias in estimates of $g_0(s)$ (cont'd)

Recall, 
$$I(t) \sim \text{Pois}\left(R_0 \sum_{s=1}^t g_0(s)I(t-s)\right)$$

where  $I(0), \ldots, I(t)$  grows, typically exponentially

How are estimates of  $R_0$  (or predictions  $I(1), \ldots, I(t)$ ) affected by the generation time distribution  $\{g_0(s)\}$ ?

Recall, 
$$I(t) \sim \text{Pois}\left(R_0 \sum_{s=1}^t g_0(s)I(t-s)\right)$$

where  $I(0), \ldots, I(t)$  grows, typically exponentially

How are estimates of  $R_0$  (or predictions  $I(1), \ldots, I(t)$ ) affected by the generation time distribution  $\{g_0(s)\}$ ?

It is easy to show that the mean parameter

 $R_0 \sum_{s=0}^t g_0(s) I(t-s)$  increases if:

 $-g_0(s)$  is replaced by  $\hat{g}_0(s)$  which has smaller mean

-  $g_0(s)$  is replaced by  $\hat{g}_0(s)$  which has same mean and larger variance

Recall, 
$$I(t) \sim \text{Pois}\left(R_0 \sum_{s=1}^t g_0(s)I(t-s)\right)$$

where  $I(0), \ldots, I(t)$  grows, typically exponentially

How are estimates of  $R_0$  (or predictions  $I(1), \ldots, I(t)$ ) affected by the generation time distribution  $\{g_0(s)\}$ ?

It is easy to show that the mean parameter

 $R_0 \sum_{s=0}^t g_0(s) I(t-s)$  increases if:

 $-g_0(s)$  is replaced by  $\hat{g}_0(s)$  which has smaller mean

-  $g_0(s)$  is replaced by  $\hat{g}_0(s)$  which has same mean and larger variance

So, if our estimate of  $\{g_0(s)\}$  has mean biased from below we will **under-estimate**  $R_0$ 

And if we estimate  $\{g_0(s)\}$  by something with the correct mean but larger variance we will **under-estimate**  $R_0$ 

A few slides back we showed three problems when estimating  $g_0(s)$  from **contact tracing**:

1) Looking backwards rather than forward in time:  $g_0(s)$  was biased from below ( $E(G_0)$  under-estimated)  $\implies R_0$  will be **under-estimated** 

2) What if multiple infector candidates:  $g_0(s)$  was biased from below ( $E(G_0)$  under-estimated)  $\implies R_0$  will be **under-estimated** 

3) Observing Serial intervals instead of Generation times  $g_0(s)$  has too large standard deviation ( $V(G_0)$  over-estimated)  $\implies R_0$  will be **under-estimated** 

A few slides back we showed three problems when estimating  $g_0(s)$  from **contact tracing**:

1) Looking backwards rather than forward in time:  $g_0(s)$  was biased from below ( $E(G_0)$  under-estimated)  $\implies R_0$  will be **under-estimated** 

2) What if multiple infector candidates:  $g_0(s)$  was biased from below ( $E(G_0)$  under-estimated)  $\implies R_0$  will be **under-estimated** 

3) Observing Serial intervals instead of Generation times  $g_0(s)$  has too large standard deviation ( $V(G_0)$  over-estimated)  $\implies R_0$  will be **under-estimated** 

**Conclusion**: Unless taken account for, all three problems make  $R_0$  *under-estimated*. See Britton & Scalia-Tomba (Interface, 2019)

#### Biases for Ebola and COVID-19

For Ebola 75% of contacts had multiple potential infectors. The combinded under-estimation of  $R_0$  was  $\approx 23\%$ 

For Corona (Covid19) there was no information of multiple infectors (but I am sure there were!), so only considering bias from backward tracing we believe  $R_0$  is under-estimated by  $\approx 12\%$ .

## The current (or daily) reproduction number $R_t$

Later on in the epidemic infected individuals no longer infect on average  $R_0$  new individuals for two reasons:

- Some individuals are immune (due to infection and/or vaccination)

- Preventive measures of various forms may have reduced contacts, transmission risks and/or period of infection

If a fraction of immune individuals equals i and the overall reduction in infectious contacts by all preventive measures equals p, then the current reproduction number  $R_t$  around calendar time t equals

$$R_t = R_0(1-i)(1-p)$$

## Estimating $R_t$ from recent incidence

However, if we observe incidence around time t and know the current generation time distribution  $g_t(\cdot)$ , we can estimate  $R_t$  directly from

$$I(t) \sim \operatorname{Pois}\left(R_t \sum_s g_t(s)I(t-s)\right), \qquad (**)$$

(averaging over a few days around t).

But usually  $g_t(\cdot)$  replaced by  $g_0(\cdot)$  (the initial generation time distribution) ...

#### GTD changes when preventive measures are adopted

Favero, Scalia Tomba and Britton (2022)

During covid-19 pandemic preventive measure have been enforced and we have changed behaviour:

- 1. Social distancing in general
- 2. Self-isolation upon symptoms
- 3. Screening testing
- 4. Contact tracing diagnosed cases

All of these reduce the daily reproduction number  $R_t$  (the average number of infections made by an infected now)

But some also change the timing when infections happen, so changes the  $\ensuremath{\mathsf{GTD}}$ 

#### A model to investigate effect of prevention on GTD

#### Contact process:

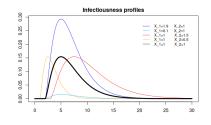

$$C = \{C(t)\}_{t \ge 0}$$
 with  $C(t) = \begin{cases} C_1, & \text{if } t \le \tau \\ C_2, & \text{if } t > \tau \end{cases}$ 

 $C_1$ : base contact rate (r.v)  $C_2$ : reduced contact rate (r.v)  $\tau$ : reduction-time (r.v) e.g. onset or detection Different definitions of  $\tau$ ,  $C_1$ ,  $C_2$ , allow modelling contacts in several scenarios, with or without interventions

#### Infectiousness process:

$$\begin{split} &X = \{X(t)\}_{t \geq 0} : \text{ probability of} \\ &\text{infection at time } t \text{ (given a contact)} \\ &\text{e.g. } X(t) = p\mathbb{I}_{[0, l]}(t) \text{ (SIR)} \\ &\text{Our focus: } X(t) = X_1 h(X_2 t), \\ &h \text{ deterministic function, } X_1, X_2 \text{ r.v.'s} \end{split}$$

**Infectivity proc:**  $\lambda(t) = C(t)X(t)$ 

#### Effects of various preventions:

Infectivity function:  $\beta(t) = E(C(t)X(t))$ 

Basic reproduction number:  $R_0 = \int_0^\infty \beta(t) dt$ 

Generation time density (GTD):  $f_G(t) = \beta(t)/R_0$ 

Various preventions (all reduce *R* but): Overall contact-reduction:  $C \rightarrow \rho C$  (no effect on GTD!) Face masks:  $X(\cdot) \rightarrow \rho X(\cdot)$  (no effect on GTD!) Isolation of symptomatic/confirmed:  $C_2 \rightarrow \rho C_2$  (reduces GTD!)

**Screening**:  $\tau = \min\{T_{Sympt}, T_{scre}\}$  (reduces GTD!)

**Contact tracing**:  $\tau = \min\{T_{Sympt}, T_{CT}\}$  (reduces TGD!)

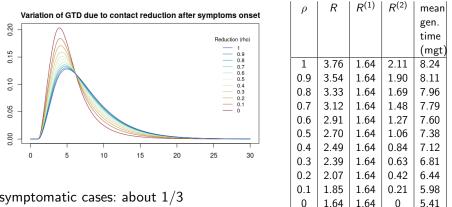

Effects on GTD depends on model assumptions and is quite complicated, in particular contact tracing

Estimating  $R_0$  during the early stage of an outbreak Estimating  $R_t$ , the current reproduction number

#### Illustration: Isolating symptomatic individuals

$$\tau = T_S \quad C_2 = \rho C_1 \quad X(t) = X_1 h(tX_2)$$

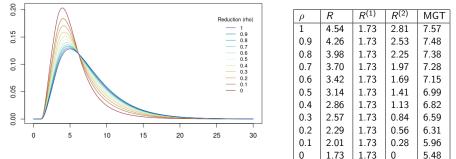

Asymptomatic cases: about 1/3

Example:  $\rho: 0.5 \rightarrow 0.1$  implies R reduced by 31% and mgt by 19%

#### Illustration: Isolating symptomatic individuals

$$au = T_S$$
  $C_2 = 
ho C_1$   $X(t) = X_1 h(tX_2)$  MGT= mean generation time

#### Variation of GTD due to contact reduction after symptoms onset

Asymptomatic cases: about 1/3

Example: ho: 0.5 
ightarrow 0.1 implies R reduced by 36% and mgt by 15%

## Covid example and effect on bias

Combining preventions (added isolation, screening and CT) where we have "guessed" suitable values reduces

 $R = 3.9 \rightarrow R = 1.45$  (reduction by 62%)

$$E(G) = 7.4 \rightarrow E(G) = 5.8$$
 days (reduction by 22%)

#### Inferring R<sub>t</sub>

Suppose we observe (increasing) incidence  $\{I(t)\}$  for this situation  $(R_t = 1.45 \text{ and mean gen-time } E(G) = 5.8)$ 

If we use this new correct GTD and apply Euler-Lotka estimating equations we get  $\hat{R}_t\approx 1.45$  as it should

However, if we instead used the original GTD with mean 7.4 days (as most do!) we would get  $\hat{R}_t \approx 1.75$ , so biased by > 20%

 $R_t$ -estimates that use early GTD-estimates are biased from above (or more accurately "biased away from 1")

# Thanks for your attention!
